A prediction of a difference in the magnetic moments of the positron and electron:

As mentioned in a previous draft (<https://doi.org/10.5281/zenodo.14788393>):Space elementary quantum(SEQ) has a ground state with ground energy(such as ground state spin form or vibration form), if ground state spin chirality is fixed, this can be one possible explanation on the phenomenon of parity non conservation. The ground-state energy of Space Elementary Quantum (SEQ) can also explain the cosmological constant in general relativity.”

If a slight difference is measured between the magnetic moment of the positron and that of the electron, it would strengthen the credibility of the hypothesis that the SEQ has a ground-state spin. This is because the rotational manner of the positron's structural matrix differs from that of the electron's structural matrix, leading to distinct couplings with the SEQ's ground-state spin. Based on this, it can be inferred that the magnetic moments of the positron and electron should exhibit a slight discrepancy.

Moreover, if a difference in the magnetic moments of the positron and electron is experimentally measured, under the framework of SEQ, it would imply that the electron itself has a dynamic structure composed of SEQ components.
